Abstract

Based on their proposed metabolic effects, we examined whether fish oil (FO) and SCFA, alone or in combination, accelerate weight loss and the resultant metabolic improvements. Obesity was induced in male C57BL/6J mice by high-energy feeding for 10 weeks. The mice were transferred to a low-fat diet (2.5w%) for 4 weeks, the source of fat being either FO, a lard–safflower oil mix (control), or both types combined with SCFA. Weight, fasting insulin, tissue and serum lipid concentrations, as well as mRNA amount of genes related to adipose inflammation and hepatic fat oxidation were determined. All groups lost weight and showed reduced fasting insulin concentrations and reduced liver TAG. However, weight loss on the control-fat diet caused significant increase in hepatic and cardiac NEFA. Substituting 20% of the fat with SCFA increased weight loss by 48% and reduced fasting insulin 1.5-fold more than the no-SCFA diets. It furthermore significantly increased the amount of mRNA for PPAR- α , and decreased the mRNA amount for NF- κ B in the liver and white adipose tissue. The FO diets enhanced improvement of tissue lipid levels. Thus, FO improved liver TAG and NEFA levels compared with weight loss on the control diet. Combining FO and SCFA further reduced tissue NEFA accumulation. In conclusion, we found that dietary SCFA had a significant impact on gene expression in the liver and adipose tissue, and that the effect of FO on tissue NEFA content was modified by SCFA. Thus, interactions between fatty acids should be considered when studying the effects of specific fatty acids.

Key words: Acetate: SCFA: Fish oil: Weight loss: Tissue NEFA

Dietary fatty acid chain length and degree of unsaturation are believed to influence the development of insulin resistance and *n*-3 long-chain (LC)-PUFA are particularly interesting due to their proposed anti-inflammatory and lipid-modulating effects. Weight loss is also expected to improve insulin sensitivity, restore normal function of the adipose tissue and reduce the level of inflammatory mediators. We therefore hypothesised that the addition of fish oil (FO) to a weight loss diet could improve the recovery of healthy metabolic function due to combined beneficial effects, including a potential increase in the rate of weight loss as indicated from studies with human test subjects^(1–3).

Several recent studies indicate that pro-inflammatory mediators produced in the adipose tissue promote the development of insulin resistance⁽⁴⁾. Fat-laden adipocytes excrete mediators that attract and activate macrophages^(5–7), which, in turn, excrete a number of inflammatory molecules including TNF- α ⁽⁸⁾. TNF- α has been implicated to directly attenuate the insulin response in skeletal muscle cells, adipocytes and

hepatocytes^(9–11) and several molecular mechanisms have been suggested to link TNF- α to insulin resistance; for example, a direct inhibition of insulin-receptor autophosphorylation⁽¹¹⁾. Furthermore, it has been shown that TNF- α can increase lipolysis, causing an increased flow of NEFA from adipocytes to non-adipose tissues, which is also expected to reduce insulin sensitivity in both skeletal muscles and the liver⁽¹²⁾.

A beneficial effect of FO on adipose inflammation in db/db mice on a high-fat diet has been shown by Todoric *et al.*⁽¹³⁾. Furthermore, Krebs *et al.*⁽¹⁴⁾ found additional improvements in metabolic risk factors in women who consumed FO while losing weight. A plausible mechanism behind this effect could be that *n*-3 LC-PUFA or their metabolites activate PPAR, which leads to the induction of anti-inflammatory pathways. PPAR- γ activation has been shown to reduce the production of TNF- α ⁽¹⁵⁾. PPAR- γ and PPAR- α activation has also been shown to inhibit the activation of NF- κ B, which is a key pro-inflammatory regulator⁽¹⁶⁾. PPAR- α is also a key regulator of genes involved in lipid oxidation and its activation

Abbreviations: Ctrl, control; FO, fish oil; GPR, G-protein-coupled receptor; LC-PUFA, long-chain-PUFA; SREBP-1c, sterol regulatory element binding protein-1c.

by dietary *n*-3 LC-PUFA may thus reduce the lipid load in non-adipose tissue and thereby increase insulin sensitivity⁽¹⁷⁾.

The inclusion of low-energy fat in exchange for normal fat may be another way to enhance recovery during weight loss. Low-energy fat of the Salatrim type contains high amounts of SCFA (acetate and propionate), which reduces the energy content to about 21 kJ/g compared with 38 kJ/g in normal dietary fat⁽¹⁸⁾. Furthermore, SCFA have been shown to induce the expression of PPAR- α and reduce the expression of NF- κ B in a cell model⁽¹⁹⁾, indicating that SCFA might have anti-inflammatory activity. Interestingly, acetate, the main organic acid in Salatrim, was found to exert strong anti-inflammatory activity through the activation of the G-protein-coupled receptor 43 (GPR43; also called NEFA receptor-2)⁽²⁰⁾. GPR43 has been identified as a specific receptor for SCFA, and is mainly expressed in white and brown adipose tissue, the large intestine, dendritic cells and granulocytes^(20,21). In the white adipose tissue, GPR43 activation has been implicated in the regulation of lipid and glucose homeostasis and is today exploited as a promising drug target for the treatment of insulin resistance and type 2 diabetes⁽²²⁾. Furthermore, it was also recently shown that activation of GPR43 in immune cells is required for normal resolution of certain inflammatory responses⁽²¹⁾. Thus, combining Salatrim with FO may result in synergism from the concomitant increase in PPAR- α expression and increased availability of its *n*-3 LC-PUFA agonists, as well as the anti-inflammatory effects and metabolic improvements in adipose tissue induced by the activation of GPR43.

The primary hypothesis of the present study was that obese mice on a hypoenergetic diet enriched with FO show improved rate of weight loss and greater improvements in metabolic risk factors compared with mice on a similar diet low in *n*-3 LC-PUFA. We furthermore explore the hypothesis that SCFA from Salatrim and *n*-3 LC-PUFA from FO have synergistic beneficial effects on metabolic function, enhancing the rate of which it returns to a lean phenotype during weight loss. Metabolic function was assessed by weight, fasting insulin, tissue lipid content and transcription of genes related to inflammation and lipid turnover.

Methods

Animals and diets

A total of forty-eight male C57BL/6J mice weighing 22.3 (SD 1.1) g (Charles River Laboratories International, Wilmington, MA, USA) were randomised into six groups. A lean reference group (lean) was kept on standard diet 1324 from Altromin (Lage, Germany) for the entire feeding period. In the five remaining groups, obesity was induced by feeding a high-energy diet for 10 weeks (60 energy% fat) (D12492; Research Diets, New Brunswick, NJ, USA) and by the addition of 15 w% sucrose to drinking-water. Following the weight gain period, one group of mice continued on the high-fat diet to serve as an obese reference group (obese), while four groups were switched to *ad libitum* low-energy diets for 4 weeks (2.5 w% fat added to powdered C1056 diet from Altromin). There was no difference in the average weight of the five obese

groups after the weight gain period; the average was 35 g compared with 26 g in the lean reference group. The weight loss diets differed in fatty acid composition (Table 1) by the addition of either cod liver oil (FO) or a control (Ctrl) mix of lard and safflower oil (Ctrl) alone or with the exchange of 25 w% of the fat for Salatrim (FO + Salatrim, Ctrl + Salatrim) (the Salatrim was a gift from DANISCO, Brabrand, Denmark). The macronutrient composition in the four weight loss diets was identical with 611 g/kg carbohydrates, 25 g/kg fat, 172 g/kg protein, 142 g/kg free amino acids and 41 g/kg fibre. The amount of fat added to the weight loss diets corresponded to the upper levels of a realistic daily FO intake for humans. Thus, the 2.5 w% equals 6 energy%, which corresponds to a daily intake of 15 g FO for a person consuming 10 000 kJ/d. The mice were housed in groups of four in wire cages at 20–22°C, humidity between 45 and 65%, and a 12 h light cycle. All handling and use of animals in the present study were approved by The Danish Animal Experiments Inspectorate and were carried out according to the guidelines of 'The Council of Europe Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific purposes'.

Physiological and biochemical measurements

Weight was recorded weekly and fasting insulin was measured after 10 and 14 weeks. All mice were killed after 14 weeks by anaesthetisation (0.11 ml/25 g body weight of Ketaminol mixed with Narcoxyl 1000:125; Intervet Danmark AS, Skovlunde, Denmark) followed by a cardiac puncture from where all the blood was drawn. The blood was left to clot at room temperature for 20 min and the serum was collected after centrifugation. The heart, liver and adipose tissue were removed immediately and quickly frozen in liquid N₂ before transfer to a –80°C freezer. Small fractions of the liver and adipose tissue were treated with RNAlater (Invitrogen, Taastrup,

Denmark) according to the manufacturer's recommendations, prior to freezing and later RNA isolation. Serum concentrations of insulin were analysed using ELISA kits (Mercodia AB, Uppsala, Sweden). Serum concentrations of TAG and NEFA were measured using kits from Wako Chemicals (Neuss, Germany) and a Cobas Mira auto-analyzer (Roche, Basel, Switzerland). Lipids were extracted from the tissue, the serum and the feed using the Folch procedure with the addition of nonadecanoic acid, dinonadecanoyl-glycerophosphorylcholine and triheptadecanoyl as internal standards before extraction⁽²³⁾. Tissue phospholipids, NEFA and TAG were separated using preparative TLC; methyl esters of the lipids were prepared from the TLC scrapings or directly from the lipid extract of the serum and diets and separated and quantified using GLC as described earlier⁽²⁴⁾.

RNA extraction and real-time quantitative PCR

Total RNA was isolated from the hepatic and adipose tissue using TRIzol (Invitrogen) and mRNA was further isolated from the total RNA by the use of μ MACS mRNA isolation kit (Miltenyi Biotec, Bergisch Gladbach, Germany). Reagents for first strand synthesis, as well as primer sets for real-time quantitative PCR, were purchased from Superarray (Frederick, MD, USA) in the form of commercial kits including CYBR green master mix for real-time detection. Actb, Gapdh and HSP90AB1 were used as reference genes. A Biometra Tpersonal thermocycler (Biometra, Goettingen, Germany) was used for first strand production, and a Bio-Rad iCycler iQ5 was used for PCR amplification and detection (Bio-Rad, Copenhagen, Denmark). The thermocyclers were programmed according to the recommendations from Superarray. Melting curve analysis was performed to check that only one target was amplified.

Statistics

All data are presented as group mean and standard deviations. GraphPad Prism 5 (GraphPad Software, Inc., La Jolla, CA, USA) was used for statistical analysis, and significance was set at α 0.05. A two-way ANOVA was performed in order to assess the effect of fat type and Salatrime in the four weight loss diets, comparing data from these four groups only. If the ANOVA result showed a significant interaction, two-sided *t*-tests were computed to assess the differences between the individual groups. Data from the obese and lean reference groups are included in all graphs and tables for comparison.

Results

Weight loss and fasting insulin

All weight loss groups continuously lost weight and the obese reference group continued to gain weight between weeks 10 and 14 (Fig. 1(A)). Fasting insulin was changed accordingly in all groups (Fig. 1(B)). Furthermore, there was a significant correlation between the change in weight and change in fasting insulin (r^2 0.73, P < 0.0001). Salatrime caused a significant

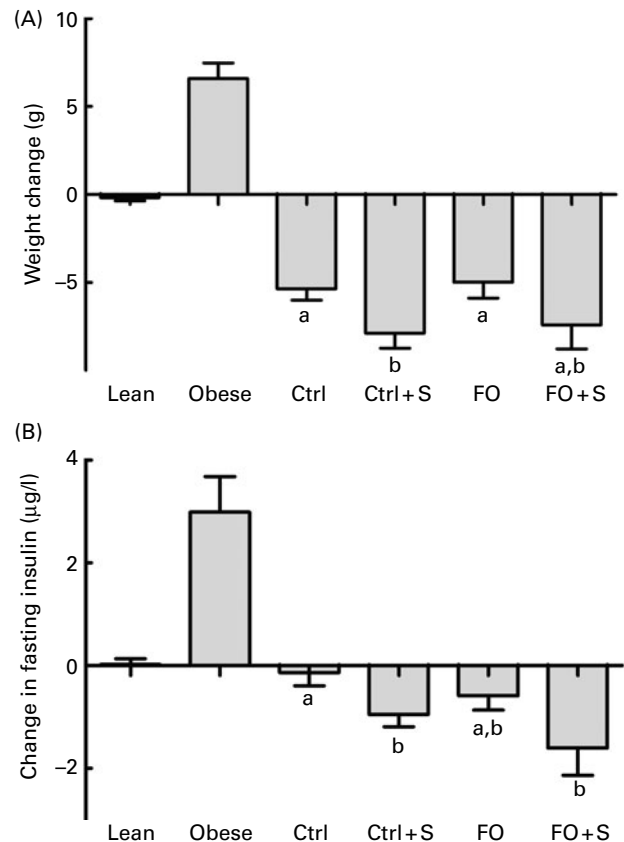

Fig. 1. The (A) weight change and (B) change in fasting insulin during the weight-loss phase (weeks 10–14) in the four weight loss groups and the lean and obese reference groups. Values are means and standard deviations, n 8. The lean and obese groups serve as reference groups for comparison and were not included in the statistical analyses. Statistical analysis was performed as a two-way ANOVA, using fish oil and Salatrime as variables. For both weight change and change in fasting insulin, two-way ANOVA showed an effect of Salatrime (P < 0.02). ^{a,b} Mean values with unlike letters are significantly different (P < 0.05). Ctrl, control diet; FO, fish oil diet; FO + S, 25% of the normal fat was exchanged for Salatrime.

increase in weight loss, whereas the weight loss and subsequent change in fasting insulin in the FO and Ctrl groups did not differ (Fig. 1).

Effects on lipid content and composition

The analysis of EPA and DHA amounts in liver TAG showed that the FO groups responded to the treatment with about sixteen times more EPA and five times more DHA incorporation compared with the Ctrl groups (Fig. 2(A)). Analysis of the adipose tissue content of EPA and DHA showed that even though the net flux of fatty acids during weight loss is assumed to be away from the adipose tissue, incorporation of the fatty acids from the FO diets had taken place (Fig. 2(B)). The hepatic phospholipid fatty acid composition and adipose tissue total fatty acid composition can be found in the online supplementary material (<http://www.journals.cambridge.org/bjn>). The concentration of TAG in the liver was reduced in both FO groups with no additional effect of Salatrime (Table 2). The serum concentration of NEFA was increased in the FO groups

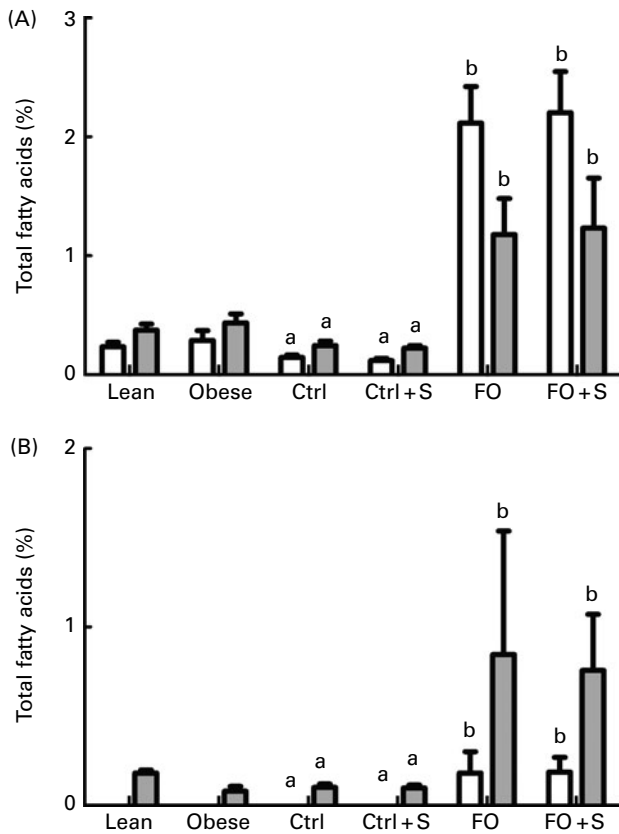

Fig. 2. The percentage of EPA (□) and DHA (■) in the (A) liver and (B) adipose tissue TAG as a percentage of total fatty acids in TAG. Otherwise as in Fig. 1. ^{a,b}Mean values with unlike letters are significantly different. Ctrl, control diet; FO, fish oil diet; FO + S, 25% of the normal fat was exchanged for Salatrim.

but the serum concentration of TAG was not affected by any of the treatments (Table 2). It is noteworthy that, in both Ctrl groups weight loss induced a substantial increase in hepatic concentrations of NEFA compared with both the obese and the lean reference groups (Fig. 3(A) and (B)). FO reduced this weight loss-induced liver accumulation of NEFA, and there was a pronounced interaction between FO and Salatrim, which reduced NEFA even further (Fig. 3(A)). Analysis of cardiac NEFA accumulation also showed significant interaction between FO and Salatrim, which resulted in

lower NEFA concentrations in the FO + S group compared with the three other weight loss groups (Fig. 3(B)).

Liver and adipose tissue mRNA amounts

The addition of Salatrim to the diets resulted in significantly higher levels of PPAR- α mRNA and lower levels of mRNA for the P65 subunit of NF- κ B in both the liver (Fig. 4 (A) and (B)) and adipose tissue (the supplementary material for this article can be found at <http://www.journals.cambridge.org/bjn>) compared with the effect of the weight loss diets without Salatrim. The Salatrim groups also had lower levels of sterol regulatory element binding protein-1c (SREBP-1c) mRNA in the liver (Fig. 4(C)). TNF- α mRNA in the adipose tissue tended to be lower in the Salatrim groups compared with the pure FO and Ctrl groups (the supplementary material for this article can be found at <http://www.journals.cambridge.org/bjn>). Neither FO nor Salatrim significantly reduced the level of CD68 mRNA, which was used as a marker for macrophage infiltration in the adipose tissue (the supplementary material for this article can be found at <http://www.journals.cambridge.org/bjn>). No significant group differences were found in hepatic mRNA amounts of the SREBP-1c-regulated enzymes; fatty acid synthase and acetyl-CoA carboxylase, which together produce fatty acids from acetyl-CoA (the supplementary material for this article can be found at <http://www.journals.cambridge.org/bjn>). Nor were there any significant differences in the mRNA amount of stearoyl CoA desaturase-1 – a key lipogenic enzyme, or in the mRNA amounts of three PPAR- α -regulated fatty acid oxidative enzymes; acyl-CoA synthetase (catalyses an initial step in long-chain fatty acid catabolism), the peroxisomal β -oxidation enzyme acyl-CoA oxidase, and the microsomal ω -hydroxylase cytochrome P450 4A10 (the supplementary material for this article can be found at <http://www.journals.cambridge.org/bjn>). The relative mRNA amounts of adipokines and genes associated with inflammation and energy metabolism can be found in the supplementary material at <http://www.journals.cambridge.org/bjn>. Salatrim treatment significantly reduced adipose mRNA levels of TGF- β , plasminogen activator inhibitor-1, leptin, resistin and the insulin receptor, and FO treatment also reduced adipose resistin mRNA.

As the two-way ANOVA showed significant interaction, pair-wise *t* tests were performed. ^{a,b} Mean values with unlike letters are significantly different between groups. The two reference groups were not included in the tests. Ctrl, control diet; FO, fish oil diet; FO + S, 25 % of the normal fat was exchanged for Salatrim.

Discussion

In the present study we have investigated how specific groups of dietary fatty acids and their interactions affect the rate of weight loss, metabolic function and risk factors related to the development of the metabolic syndrome in mice.

In our study, the inclusion of FO to a weight loss diet did not affect the rate of weight loss or fasting insulin. This is contrary to studies that have shown that the inclusion of *n*-3 LC-PUFA to a weight loss diet leads to increased rate of weight loss in humans^(1–3) and reduced fasting insulin in rodents⁽²⁵⁾. However, anti-obesity effects are not a consistent finding in humans as other studies report no effect of *n*-3 LC-PUFA on the rate of weight loss^(26,27), whereas in rodents, the anti-obesity as well as insulin-reducing effects of *n*-3 LC-PUFA have been highly consistent during weight gain^(28–33). However, as our primary focus was to study the effects of a FO intake realistic for a human population, we have used substantially lower concentrations than earlier studies. Nakatani *et al.*⁽²⁸⁾ compared the effect on weight gain of different amounts of FO fed to female C57BL/6J mice, and found that less than 40 energy% FO was insufficient in reducing weight gain significantly compared with the no FO control. We gave the mice 4.5–6 energy% FO, which corresponds to 12–15 g/d of FO for a person consuming 10 000 kJ/d, and higher intake might be unrealistic in a human nutritional context.

Furthermore, in contrast to earlier studies when FO was given during weight gain, we can also expect dilution of the fatty acids of dietary origin with fatty acids released from the adipose tissue during weight loss in the present study. Therefore, it is noteworthy, that the low doses used have been sufficient to improve hepatic and cardiac lipid status, proving that FO intake at these relatively low levels also improves metabolic status during weight loss.

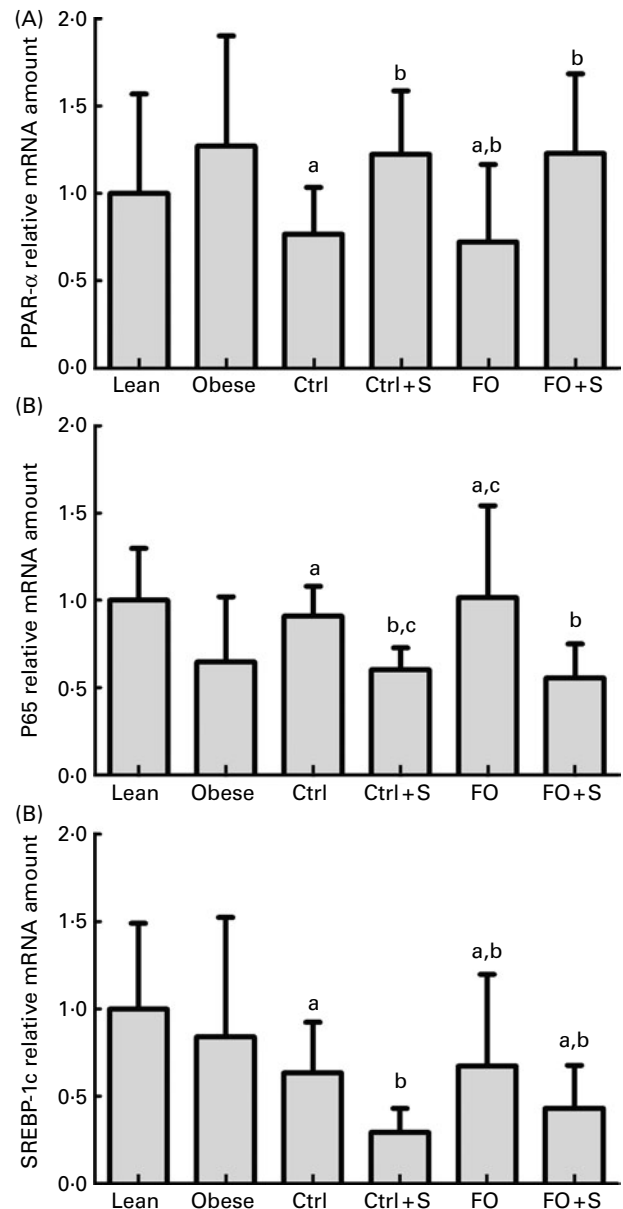

Fig. 4. The relative hepatic mRNA amount of (A) PPAR- α , (B) NF- κ B subunit P65 and (C) sterol regulatory element binding protein-1c (SREBP-1c) in the four different weight loss groups and the reference groups. The real-time quantitative PCR data are presented as mean and standard deviations relative to the mRNA level in the lean reference group, *n* 8. The two-way ANOVA includes only the four weight loss groups. For the relative hepatic mRNA amounts of PPAR- α , P65 and SREBP-1c, two-way ANOVA showed an effect of Salatrim of $P < 0.004$, $P < 0.002$ and $P < 0.003$, respectively. ^{a,b,c} Mean values with unlike letters are significantly different between individual groups. Ctrl, control diet; FO, fish oil diet; FO + S, 25 % of the normal fat was exchanged for Salatrim.

Dietary *n*-3 LC-PUFA have been shown to prevent the development of insulin resistance in rodents when obesity is induced by a high-energy diet^(29,33–35), but the effect of administering *n*-3 LC-PUFA to obese animals during weight loss has, to our knowledge, not previously been investigated. A study by Ramel *et al.*⁽³⁶⁾ indicated that physiological doses of FO (3 g/d) during weight loss would improve insulin sensitivity in humans, and in the present study we wanted to investigate the potential mechanisms for this effect. We hypothesised that the proposed anti-inflammatory effects of *n*-3 LC-PUFA could lead to a reduction of the inflammatory state of the adipose tissue, and that the activation of hepatic PPAR- α by *n*-3 LC-PUFA could induce the transcription of fat-oxidising enzymes and thus reduce hepatic lipid accumulation. Both of these effects were expected to improve insulin sensitivity, but no difference was seen in fasting insulin after 4 weeks on a FO diet compared with the Ctrl group that did not consume FO. Total macrophagal infiltration in the adipose tissue was assessed by the amount of mRNA encoding CD68, a macrophage surface receptor, and this was also not reduced by FO treatment. Total macrophagal infiltration, however, does not give information on the activation state of the adipose tissue macrophages, but as anti-inflammatory effects of FO on the amount of mRNA encoding TNF- α or NF- κ B P65 were not found, an effect on the distribution between inflammatory M1- and anti-inflammatory M2-tissue macrophages is unlikely.

Hepatic NEFA and TAG accumulation was reduced by FO relative to the Ctrl fat, and in both cardiac and hepatic tissue the combination of FO and SCFA was particularly efficient in reducing NEFA accumulation. This shows that inclusion of FO and SCFA in weight loss diets might be a feasible strategy to optimise the improvement in tissue lipid status during weight loss. The increased load of NEFA in tissues is strongly linked to the accumulation of lipotoxic fatty acid derivatives, such as acyl-CoA, ceramide and diacylglycerol, which have been suggested to be part of the aetiology of both insulin resistance and CVD^(37,38). Hence, the increased load of cardiac and hepatic NEFA in the weight-loss groups given Ctrl fat, constitute a metabolic risk that, at least in mice, can be reduced through intervention with appropriate dietary fat during a weight-loss programme. The lipid-lowering effect of FO is consistent with the expected effect of *n*-3 LC-PUFA on PPAR- α and SREBP-1c in the liver. However, we did not find a significant increase in the mRNA amount of PPAR- α -regulated hepatic fat-oxidising enzymes that could explain this finding. Mori *et al.*⁽³²⁾ were able to find significant increases in the mRNA amount and enzymatic activity of hepatic fat-oxidising enzymes in C57BL/6J mice following 2 weeks on a FO diet. Their setup, however, differed from the present study as they fed the mice a weight-increasing diet.

In conclusion, we show that a (relatively) low-dose FO intervention is able to increase the rate of improvement of liver lipid levels during a weight-loss programme without a concomitant improvement of glucose tolerance or adipose inflammation, compared with weight loss on the Ctrl-fat diet.

We also investigated the effect of exchanging 25 w% of normal fat with Salatrim. This exchange was tried in

combination with both Ctrl fat and FO in order to investigate the possible synergistic effects of the SCFA from Salatrim and *n*-3 LC-PUFA from FO. The weight loss after 4 weeks on low-energy diets was evident for all mice, but it was significantly greater when 25% of the fat was exchanged for Salatrim. The change in fasting insulin was highly correlated to weight change and additional improvements in the Salatrim groups were probably due to the difference in weight.

However, Salatrim also affected parameters which could not be explained by the reduced energy intake and increased weight loss. The amount of PPAR- α mRNA was higher, and that of NF- κ B p65 subunit was lower in both adipose and hepatic tissues. We were able to show *in vivo* the effect of SCFA on the amount of PPAR- α mRNA, which had previously been shown only in *in vitro* experiment⁽¹⁹⁾. A higher expression of PPAR- α could explain the combined effect of SCFA and *n*-3 LC-PUFA on hepatic and cardiac NEFA levels. The transcription of many lipogenic enzymes is controlled by the transcription factor SREBP-1c, and a reduction in its activity could also lead to reduced fatty acid accumulation. We found a significant reduction in the amount of mRNA encoding this transcription factor following Salatrim treatment, but again without significant reductions in the amount of mRNA-encoding lipogenic enzymes under its control.

The source of SCFA in the present study was Salatrim, but fermentation of fibre by the gut microflora provides a natural source of SCFA, which has been measured to be 375 mmol/l in the human portal vein⁽³⁹⁾. The finding that acetate and propionate in Salatrim seem to act as systemic transcriptional regulators therefore has more wide-reaching implications as it suggests that some of the systemic effects induced by interventions with pre- or probiotics might be explained by enhanced production of SCFA. Cell studies have shown reduced cytokine production following LPS stimulation of SCFA-treated neutrophils, and SCFA have furthermore been shown to inhibit the activity of NF- κ B *in vitro*. The present results, showing lower hepatic and adipose transcription of NF- κ B p65 in the SCFA-treated mice, indicate that SCFA could also inhibit NF- κ B activity *in vivo*, and that those anti-inflammatory effects of SCFA could reach the systemic circulation, although evidence of reduced inflammation was not found in the present study. Yin *et al.*⁽⁴⁰⁾ have shown that SCFA treatment reduced I κ B (NF κ B inhibitor degradation after NF- κ B stimulation *in vitro*, and it is possible that SCFA inhibit NF- κ B activity by more than one pathway. Systemic inflammation is associated with the metabolic syndrome, and it is possible that SCFA mediate some of the beneficial effects of fibre consumption by its anti-inflammatory properties. An effect of SCFA on gene transcription could be mediated by the receptors, GPR41 and GPR43, which are widely distributed, although most commonly associated with adipocytes and immune cells⁽²¹⁾. SCFA have previously been shown to signal through these receptors⁽⁴¹⁾.

In conclusion, the addition of FO to a low-fat diet during weight loss did not reduce adipose inflammation and fasting insulin. However, exchanging 25 w% of the fat with Salatrim increased weight loss, lowered fasting insulin and altered the amount of mRNA encoding three important transcription

factors, PPAR- α , NF- κ B and SREBP-1c, which are central in inflammatory response and fatty acid metabolism. However, the most important finding of the present study is the pronounced synergistic effect of FO and Salatrims on tissue NEFA, since a reduction in available NEFA may affect the concentration of lipotoxic fatty acid metabolites that have been implicated in the development of insulin resistance and CVD.

Acknowledgements

We thank Jannie Felskov Agersten and Pernille Wehler Göllich for technical assistance and DANISCO for financial support and for kindly providing us with the Salatrims used in the present study. This work was financially supported by the Danish Council for Strategic Research through the Program Committee for Food and Health, and DANISCO did not have any influence on the interpretation of the data or the writing of this paper. M. H. P., L. L. and L. I. H. have no conflict of interests. M. H. P. conducted the experiments and wrote the paper. L. I. H. developed the overall research plan in collaboration with L. L. All authors share responsibility of the final content.
